# Mortality Among Children with Sickle Cell Disease Identified by Newborn Screening During 1990–1994 — California, Illinois, and New York

MORBIDITY AND MORTALITY WEEKLY REPORT

Sickle cell disease (SCD) is an autosomal recessive disorder characterized by production of abnormal (sickle) hemoglobin, resulting in anemia, susceptibility to pneumococcal and other infections, pain, stroke, and multiple organ dysfunctions. The most common types include hemoglobin SS (homozygous) disease, sickle cell-hemoglobin C disease, and the sickle beta-thalassemia syndromes (1). A randomized controlled trial published in 1986 indicated that daily oral penicillin prophylaxis reduced the incidence of serious infection in young children with SCD and led to widespread adoption of newborn screening programs for SCD (2). To study the effectiveness and utilization of prevention programs among large populations of infants with SCD, several newborn screening programs in the United States are now attempting to determine rates of complications and actual use of early medical interventions (e.g., penicillin prophylaxis and pneumococcal vaccination). This report focuses on recent mortality in California, Illinois, and New York. In California and Illinois, mortality from all causes among black children born during 1990–1994 with SCD was slightly less than overall mortality for all black children born in the same time period.

All newborns in California, Illinois, and New York are screened for hemoglobinopathies. Health departments implemented screening programs in New York in 1975, Illinois in 1989, and California in 1990. For this investigation, SCD was defined as any clinically significant sickle hemoglobinopathy in an infant born during 1990–1994. In California and Illinois, identifying variables from SCD databases were matched with computerized records of state-specific death certificates for 1990–1995. In New York, all SCD-related deaths among children aged <3 years listed in state vital records for 1990–1994 were matched with the state SCD database. Additional follow-up extending through 1997 was available in California and Illinois: local physicians (i.e., through surveys) and public health nurses informed the respective state health department about the circumstances of SCD-related deaths; such information was not available in New York. Mortality rates per person-year were calculated assuming complete death ascertainment through December 31, 1994, in New York and through December 31, 1995, in California and Illinois.

During 1990–1994, a total of 2487 children with presumed or confirmed SCD were identified by the three newborn screening programs. Excluding two deaths of children

# U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES

#### Sickle Cell Disease — Continued

presumably born in other states, 27 deaths were reported among children with SCD; 20 death certificates provided causes that included SCD or other conditions related to SCD (Table 1). The median age at death for the 20 infants who had SCD-related deaths was 22 months (range: 2–53 months). Mortality rates for each state were similar. In California and Illinois, where mortality for all causes was ascertained, by the end of 1995 the cumulative mortality rate was 1.5 per 100 black children with SCD born during 1990–1994. The equivalent cumulative mortality rate for all black children born during this period in California and Illinois was 2.0 per 100 black newborns, based on approximate age-coded data in national multiple-cause mortality files (*3*).

Mortality data was available until the third birthday for the subgroup of 768 children with presumed or confirmed hemoglobin SS disease born during 1990–1991 in New York and during 1990–1992 in California and Illinois. Of these 768 children, 1.0% died as a result of SCD-related causes during the first 3 years of life (0.35 per

TABLE 1. Sickle cell disease (SCD)\*-related deaths<sup>†</sup> among children born during 1990–1994, by state and year of birth, age at death, and cause of death — California and Illinois (1990–1997) and New York (1990–1994)

\*All children had presumed hemoglobin SS (homozygous) disease, except one child with sickle cell-hemoglobin C disease who died at age 53 months.

<sup>†</sup>The following deaths were excluded: three children aged <1 month whose deaths were attributed to extreme prematurity or birth defects; one child aged 42 days who died because of pneumocystosis; one child with presumed sickle-beta thalassemia who died at 47 days of age because of pneumonia; one child with cerebral palsy and seizures whose death was attributed to aspiration pneumonia; and one child who had a traumatic death.

<sup>§</sup>In addition to SCD. For 11 children, only SCD was listed as a cause of death.

#### Sickle Cell Disease — Continued

100 person-years, based on 2258 person-years [95% confidence interval=0.15–0.70 per 100 person-years]). The rate of compliance with penicillin prophylaxis was unknown; an investigation of risk factors is being conducted to analyze this and other factors in relation to death and other serious complications. Information about risk factors will be obtained through parental and physician surveys.

**Editorial Note**: The findings in this report indicate low mortality rates for children with SCD born during the early 1990s in geographic areas in which infants with the condition are identified soon after birth. Early diagnosis is an important component of comprehensive medical care for affected children (*1,4*). In a study of U.S. death certificates for 1968–1992, mortality among black children aged 1–4 years who had SCD declined significantly (*5*). This trend occurred at the same time as the establishment of newborn screening programs, more comprehensive care and parental education, wide-spread acceptance of penicillin prophylaxis after publication of the randomized trial in 1986, and new vaccinations.

Although the mortality rate for children with hemoglobin SS disease described in this report is lower than comparable rates in earlier studies, comparisons between these mortality rates and those from clinical studies, the Cooperative Study of SCD, and national death certificates must be interpreted cautiously because of differences in study design and ascertainment of deaths (5–7). One limitation of this investigation is that deaths outside the three states would not have been ascertained. Underascertainment of deaths also could have occurred through errors in matching or reporting of vital statistics. This study was population-based, and mortality rates were relatively stable because of the large number (2487) of young children with SCD.

In Maryland, the mortality rate for black children with SCD was comparable to, or lower than, the mortality rate for all black children during 1985–1994 (8). Underascertainment of SCD among severely ill neonates could account for this finding, but ill children in neonatal intensive-care units usually are screened for SCD. In California, Illinois, New York, and Maryland, comprehensive medical care and public health interventions may have contributed to the observed reduction in premature mortality from all causes.

Newborn screening follow-up studies are useful for evaluating the prevention effectiveness of public health programs, which is an essential component of applying genetic technology to disease prevention (9). Follow-up studies can determine whether public health programs that are widely implemented have the prevention impact that the randomized trials predicted. Continued evaluation over time of comparable data for hemoglobinopathies and other newborn conditions can provide epidemiologic evidence of the clinical value of screening programs for these conditions. More detailed analysis of risk factors for adverse outcomes among children who have SCD also will assist public health agencies with targeting prevention programs for specific high-risk groups.

# Human Exposure to Brucella abortus Strain RB51 — Kansas, 1997

On May 26–27, 1997, nine persons (a farmer, four veterinary clinicians, and four veterinary students) in Manhattan, Kansas, participated in an attempted vaginal delivery, a cesarean delivery, and a necropsy on a stillborn calf that died because of *Brucella abortus* infection. The infection was confirmed by isolation of *B. abortus* from placental and fetal lung tissue cultures. The National Animal Disease Center, U.S. Department of Agriculture (USDA), identified the *B. abortus* isolate from the calf as the RB51 vaccine strain. RB51 is a live, attenuated strain that was licensed conditionally by the Veterinary Services, Animal and Plant Health Inspection Service, USDA, on February 23, 1996, for vaccination of cattle in the United States.\* Before 1996, vaccine was made by using the S19 strain. This report describes occupational exposure to animals infected with the RB51 strain and emphasizes the need for surveillance of unintentional exposure of humans to RB51 to assess outcomes of such exposures.

The vaccine had caused active *B. abortus* infection because the 14-month-old heifer delivering the calf was not known to be pregnant when she was vaccinated with RB51 at approximately 8 months of age, which was within the specified age range for vaccination. The heifer was administered the RB51 vaccine dosage recommended for calves, which was 10 times the dosage recommended for adult or pregnant cattle.

The heifer was euthanized after surgery because of the poor prognosis following a uterine rupture and the poor general condition of the animal. Necropsy findings included diffuse placentitis in the heifer and fetal pneumonitis. Evidence that intrauter-

<sup>\*</sup>The vaccine was licensed conditionally to allow accumulation of additional data on field use under controlled conditions.

## Vol. 47 / No. 9

## Brucella abortus — Continued

ine infection was caused by the RB51 vaccine strain, and not by field strains of *B. abortus* or by S19, included immunohistochemical staining specific for RB51 (negative for S19), RB51-specific titer of >1:10,000 on experimental dot-blot assay measuring antibody to RB51, and RB51-specific DNA sequences identified by polymerase chain reaction (PCR).

Persons at risk for infection with RB51 were those who contacted the calf, placenta, blood, or amniotic fluid without wearing gloves, masks, or eye protection. Six women and three men (age range: 23–45 years) were at risk for infection. None of the exposed persons reported having previously had brucellosis or being unintentionally inoculated with *Brucella* vaccine.

Within 1 week after exposure, eight of the nine persons started a prophylactic regimen of doxycycline (100 mg twice daily for 21–24 days). Three of these persons also received rifampin (600 mg once daily for 4–21 days). None of the exposed persons showed signs or symptoms consistent with brucellosis during the 6-month follow-up period.

Since conditional licensure of the RB51 vaccine, 32 instances of unintentional inoculation or conjunctival exposure to the RB51 vaccine have been reported to the vaccine manufacturer or CDC. Three of the 32 persons, all of whom were unintentionally inoculated while vaccinating cattle, reported inflammation at the inoculation site; another person reported intermittent fever, chills, headache, and myalgia and had elevated levels of serum transaminase and lactate dehydrogenase.

Meningitis and Special Pathogens Br, Div of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, CDC.

**Editorial Note**: Brucellosis, also known as "undulant fever" or "Bangs disease," is a systemic infection caused by *Brucella* sp., small Gram-negative coccobacilli that can infect cattle (infection with *B. abortus*), goats and sheep (*B. melitensis*), pigs (*B. suis*), and dogs (*B. canis*). Worldwide, brucellosis usually occurs in geographic areas with large populations of these animal hosts (1,2). Disease manifestations in animals depend on age and gestational status. The primary sign of infection in female animals is abortion, and in male animals, epididymitis.

Brucellosis in humans is a systemic disease that has an acute or insidious onset; signs and symptoms of the disease include continued, intermittent, or irregular fever of variable duration; headache; weakness; profuse sweaty chills; arthralgia; depression; weight loss; and generalized aches (3). The disease can persist for periods ranging from days to years if not treated properly. *B. abortus* RB51 infection in humans is possible but has not been documented.

Through a cooperative state and federal effort, the United States is now approaching eradication of the field strain of *B. abortus* in domestic cattle and bison herds. In the United States, the Brucellosis Eradication Program (BEP) was established formally in 1954 to prevent the considerable economic losses caused by abortions that occurred before, or in the absence of, prophylactic vaccination and to reduce transmission of the disease to humans. Vaccination against brucellosis and testing or depopulation of affected herds have reduced the number of infected cattle herds in the United States. From 1952 to January 1998, the number of known brucellosis-

# Brucella abortus — Continued

affected herds decreased from 124,000 to 15, and annual losses resulting from abortions, decreased milk production, and reduced breeding efficiency decreased from approximately \$400 million to approximately \$2.5 million (unadjusted for inflation). In 1996, approximately 5.5 million calves were vaccinated against brucellosis, 11.8 million cattle were tested, and 112 affected herds were depopulated at a total cost of approximately \$20.3 million (USDA, unpublished data, 1998). Because these efforts have been successful, the BEP has set a goal of eliminating brucellosis in domestic cattle in the United States by the end of 1998. Bison and elk in the northern Rocky Mountain states are still important reservoirs of *B. abortus* and provide a potential for reintroduction of brucellosis into domestic livestock (*4*).

One element of the cooperative state and federal brucellosis eradication efforts is the use of approved *Brucella* vaccines on female cattle and female bison. The RB51 vaccine strain, a genetically stable, rough morphology mutant of *B. abortus* strain 2308 that lacks the polysaccharide O-side chain on the surface of the bacteria, replaced the S19 vaccine in 1996 (*5*). The RB51 vaccine is used in 49 states,<sup>†</sup> Puerto Rico, and the U.S. Virgin Islands; it was developed by serial passage in selective media, which resulted in a strain that was equally immunogenic, but less virulent, than the S19 vaccine. In mice, sheep, and cattle, RB51 protects against experimental challenge with *B. abortus* (*6*) and is less abortifacient than S19 if administered during pregnancy; abortions have been reported rarely among cattle vaccinated during midgestation (*7*).

Vaccination with RB51 does not result in measurable antibody titers to *B. abortus* using standard diagnostic tests. This is an important feature for use in efforts to eradicate brucellosis in domestic cattle. Strain 19 causes vaccinated animals to produce antibodies that are indistinguishable on standard diagnostic tests from the antibodies produced by animals infected with *Brucella*. Because the RB51 vaccine does not cause vaccinated cattle to produce interfering antibody titers, replacing the S19 vaccine with the RB51 vaccine will eliminate the costs associated with the retesting and tracebacks of false-positive reactors. The estimated combined field and laboratory gross savings from using RB51 vaccine total almost \$7.45 million per year.

Detection of possible human infection with the RB51 vaccine strain and development of recommendations for chemoprophylaxis are complicated by two characteristics of the new vaccine strain. First, immunologic response to the RB51 strain is not detected on routinely available serologic tests for Brucella. Experimental dot-blot assay employed for serologic measurement of RB51 postvaccination titers has been evaluated under experimental and field conditions in cattle, but this assay has not been validated by using human serum (8). This assay and PCR are being developed by CDC's Special Bacteriology Reference Laboratory for detection of human RB51 infection. Second, RB51 was derived by selection in rifampin-enriched media and is resistant to rifampin in vitro. For postexposure prophylaxis against the previously used live Brucella (S19) vaccine, CDC recommended concomitant regimens of doxycycline and rifampin. Recommendations for antibiotic selection and treatment duration for postexposure prophylaxis to RB51 are difficult to make because virulence of the strain in humans is unknown, and the strain is resistant to rifampin in vitro. If the RB51 strain poses a risk for human infection, the chemoprophylaxis recommendations will require modification. A reasonable interim course of postexposure prophylaxis for adults

<sup>&</sup>lt;sup>†</sup>Pending depletion of remaining stores of the previously used standard vaccine.

#### Vol. 47 / No. 9

#### MMWR

# Brucella abortus — Continued

would be doxycycline 100 mg orally twice daily for 21 days, with addition of other suitable antimicrobials if evidence of infection appears.

Veterinarians and other animal health-care personnel should be made aware of the possible risk for infection associated with the veterinary use of RB51. The epidemiologic conditions leading to possible infection in farmers and veterinarians are not unusual. Using the estimated rate of unintentional needlestick injuries among health-care workers in U.S. hospitals (9) as a surrogate for unintentional inoculations with RB51, at least 11,000 needlestick injuries per 5.5 million injections (i.e., the number of *Brucella* vaccine doses administered in 1996) can be expected during 1 year. Exposure of farm and veterinary personnel to infected calves or placentas is another potential source of human infection, especially on farms where heifers might be vaccinated mistakenly during mid-gestation (i.e., at which time the calf fetus may be at greatest risk for postvaccination brucellosis) (7).

CDC has established a registry of human exposures to the RB51 vaccine strain; after unintentional, conjunctival, or other suspected exposure to RB51, veterinarians, clinicians, or health department personnel should contact CDC's Meningitis and Special Pathogens Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, to report the incident and discuss additional recommendations; telephone (404) 639-3158; fax (404) 639-0817.

# Self-Assessed Health Status and Selected Behavioral Risk Factors Among Persons With and Without Health-Care Coverage — United States, 1994–1995

Persons without health-care coverage are more likely to have poor health and be at greater risk for chronic disease outcomes than persons who have health-care coverage (1). In the United States, the number of persons and the proportion of the population without health-care coverage has increased each year since 1987 (2). State-specific surveillance of health-care coverage can be used to identify subgroups of the population who lack such coverage and may be at increased risk for poor health. To determine state-specific estimates of the prevalence of self-assessed health status and risk factors for chronic disease by health-care coverage status among adults aged 18–64 years, CDC analyzed data from the 1994 and 1995 Behavioral Risk Factor Surveillance System (BRFSS). This report summarizes the results of that analysis and indicates that adults without health-care coverage were more likely than those with health-care coverage to have poor health status, to be current smokers, and to be less physically active.

BRFSS is a state-based, random-digit-dialed telephone survey of the noninstitutionalized U.S. population aged ≥18 years. The 1995 BRFSS was conducted in the 50 states and the District of Columbia and was used to determine self-reported healthcare coverage status and the selected risk factors of cigarette smoking, physical inactivity, and self-assessed health status among adults aged 18-64 years. To assess health-care coverage status, respondents were asked "Do you have any kind of health-care coverage, including health insurance, prepaid plans such as HMOs, or governmental plans such as Medicare?" Smoking was assessed by asking "Have you smoked at least 100 cigarettes in your entire life?" and "Do you smoke cigarettes now?" Current smokers were persons who reported having smoked ≥100 cigarettes during their lifetimes and who smoke now. Physical inactivity was assessed by asking the respondent "During the past month, did you participate in any physical activities or exercises such as running, calisthenics, golf, gardening, or walking for exercise?" Persons were considered inactive during their leisure time if they answered no to this question. For the purpose of this report, the estimates for health status reflect the proportion of persons indicating either fair or poor health status. Data from the 50 states were weighted to represent state populations and used to produce point estimates; 95% confidence intervals were calculated using SUDAAN.

During 1995, the prevalence of health-care coverage varied among states and ranged from 76.9% (Louisiana) to 93.3% (Hawaii) (median: 87.0%). The median prevalence of fair-to-poor self-assessed health status was 9.0% among persons with health-care coverage and 13.8% among those without coverage; state-specific prevalences among those with coverage ranged from 5.3% (Nebraska) to 17.3% (West Virginia), and among those without coverage, from 5.0% (New Jersey) to 27.9% (Kentucky) (Table 1).

The median prevalence of smoking among those with health-care coverage was 22.8%, compared with 39.3% among those without coverage (Table 2). The median prevalence of physical inactivity was 25.1% among those with health-care coverage, compared with 31.2% among those without coverage.

Reported by the following BRFSS coordinators: J Durham, MPA, Alabama; P Owen, Alaska; B Bender, Arizona; J Senner, PhD, Arkansas; B Davis, PhD, California; M Leff, MSPH, Colorado;

**Editorial Note**: The findings in this report indicate that, in most states, more persons who are without health-care coverage consider themselves to be in poor or fair health than those with health-care coverage. In addition, persons without health-care coverage reported higher levels of physical inactivity and current tobacco use than did persons who have health-care coverage. Higher levels of smoking and physical inactivity are both important risk factors for many chronic disease outcomes (*3*).

Although the wide variation in prevalence of self-assessed health status, smoking, and physical inactivity by state may reflect, in part, differences in sociodemographic characteristics (e.g., age, race/ethnicity, income, and educational level), previous reports indicate that this variation persisted even after estimates were standardized to adjust for these differences (4). Differences in self-reported health between persons with and without coverage also may reflect factors that influence the perception of ill health (e.g., subclinical illness, lack of access to providers, and the negative effects of smoking and physical inactivity).

The findings in this report are subject to at least two limitations. First, the study excluded households without telephones; previous studies indicate substantial differences in the characteristics of persons who reside in households without a telephone compared with those who reside in households with a telephone (5). Second, these estimates were only for adults and did not include persons aged <18 years. To adequately assess the impact of the lack of health-care coverage, information about the health status of children and young persons also should be considered (6).

The BRFSS enables each state to document the proportion of its population without health-care coverage and the risk factor profile of this group. This information can be used to target subgroups for specific disease-prevention or health-promotion intervention efforts as well as for policy makers seeking to evaluate health-care changes at the state level. This information also can assist local and state health officials in anticipating the need for and planning of health-care and preventive-care services. The findings of this report and the results of previous studies that indicate that the number of insured in the United States increases annually and the uninsured are less likely to receive preventive-care services (7) underscore the need for state and national policies that facilitate the broadening of health-care coverage.

# TABLE IV. Deaths in 122 U.S. cities,\* week ending March 7, 1998 (9th Week)

U: Unavailable -: no reported cases \*Mortality data in this table are voluntarily reported from 122 cities in the United States, most of which have populations of 100,000 or more. A death is reported by the place of its occurrence and by the week that the death certificate was filed. Fetal deaths are not included. \*Pneumonia and influenza. \*Because of changes in reporting methods in this Pennsylvania city, these numbers are partial counts for the current week. Complete counts will be available in 4 to 6 weeks. Total includes unknown ages.

The Morbidity and Mortality Weekly Report (MMWR) Series is prepared by the Centers for Disease Control and Prevention (CDC) and is available free of charge in electronic format and on a paid subscription basis for paper copy. To receive an electronic copy on Friday of each week, send an e-mail message to *listserv@listserv.cdc.gov*. The body content should read SUBscribe mmwr-toc. Electronic copy also is available from CDC's World-Wide Web server at http://www.cdc.gov/ or from CDC's file transfer protocol server at ftp.cdc.gov. To subscribe for paper copy, contact Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402; telephone (202) 512-1800.

Data in the weekly *MMWR* are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the following Friday. Address inquiries about the *MMWR* Series, including material to be considered for publication, to: Editor, *MMWR* Series, Mailstop C-08, CDC, 1600 Clifton Rd., N.E., Atlanta, GA 30333; telephone (888) 232-3228.

All material in the *MMWR* Series is in the public domain and may be used and reprinted without permission; citation as to source, however, is appreciated.
